The SCT12A1 is a high efficiency synchronous boost converter with fully integrated a 13m high-side MOSFET and an 11m low-side MOSFET, supporting 2.7V to 14V input voltage range and up to 12-A switch current. The switch current limit can be adjustable with an external resistor.

The SCT12A1 adapts constant off-time peak current control to provide fast transient. An external compensation network allows flexibility setting loop dynamics to achieve optimal transient performance at different load conditions. Using MODE pin selects either Pulse Frequency Modulation (PFM) operation or f

## Overview

The SCT12A1 device is a fully integrated synchronous boost converter, which regulates output voltage higher than input voltage. The constant off-time peak current mode control provides fast transient with pseudo fixed switching frequency. When low-side MOSFET Q1 turns on, input voltage forces the inductor current rise. Sensed voltage on low-side MOSFET peak current rises above the voltage of COMP. After the inductor current reaches the peak current, the device turns off low-side MOSFET and inductor goes through body diode of high-side MOSFET Q2 during dead time. After dead time duration, the device turns on high-side MOSFET Q2 and the inductor current decreases.

## Under Voltage Lockout UVLO

The SCT12A1 features UVLO protection for voltage rails of VIN, VCC and BOOT-SW from the converter malfunctioning and the battery over discharging. The default VIN rising threshold is 2.6V typical at startup and falling threshold is 2.4V typical at shutdown. The internal VCC LDO dropout voltage is about 100mV and the device is disabled when VCC falling trips 2.1V typical threshold. The internal charge pump from BOOT to SW powers the gate driver to high-side MOSFET Q2. The BOOT UVLO circuit monitors the capacitor voltage between BOOT pin and SW pin. When the voltage of BOOT to SW falls below a preset threshold 3V typical, high-side MOSFET Q2 turns off. As a result, the device works as a non-synchronous boost converter.

## Enable and Start-up

When applying a voltage higher than the EN high threshold (maximum 1.2V), the SCT12A1 enables all functions and starts converter operation. To disable converter operation, EN voltage needs fall below its lower threshold (minimum 0.4V). An internal 800K resistor connects EN pin to the ground. Floating EN pin automatically disables the device.

The SCT12A1 features programmable soft start to prevent inrush current during power-up. SS pin sources an internal 5μA current charging an external soft-start capacitor C<sub>SS</sub> when EN pin exceeds turn-on threshold. The device uses the lower voltage between the internal voltage reference 1.2V and the SS pin voltage as the reference input voltage of error amplifier and regulates the output. The soft-start completes when SS pin voltage exceeds the internal 1.2V reference. Use equation 1 to calculate the soft-start time (10% to 90%). When EN pin is pulled low to disable the device, the SS pin will be discharged to ground.

$$\text{---} \quad (1)$$

where

- t<sub>SS</sub> is the soft start time
- V<sub>REF</sub> is the internal reference voltage of 1.2V
- C<sub>SS</sub> is the capacitance connecting to SS pin
- I<sub>SS</sub> is the source current of 5uA to SS pin

## Adjustable Switching Frequency

The SCT12A1 features adjustable switching frequency from 200kHz to 2.2MHz. To set the switching frequency, an external

by the internal sensing circuitry. Once the low-side MOSFET Q1 current exceeds the limit, it turns off immediately. An external resistor connecting ILIM pin to ground sets the low-side MOSFET Q1 peak current limit threshold. Use Equation 3 or Figure 6 to calculate the peak current limit.

$$\text{---} \quad (3)$$

where:

- $I_{LIM}$  is the peak current limit
- $R_{LIM}$  is the resistance between ILIM pin to ground.

This current limit function is realized by detecting the current flowing through the low-side MOSFET. The current limit feature loses function in the output hard short circuit conditions. At normal operation, when the output hard shorts to ground, there is a direct path to short the input voltage through high-side MOSFET Q2 or its body diode even the Q2 is turned off. This could damage the circuit components and cause catastrophic failure at load circuit.

## Load Disconnection Control (SCT Patent Filed)

For both non-synchronous and synchronous boost converter, there is a non-fully controlled current path from converter input to output load through the diode or the high-side MOSFET body diode. During start up, once VIN is present, VOUT is moved to VIN level due to the direct path from input to output even when the device is shut down or the load is not ready. The presence of unwanted output voltage before system start up sequence could cause system to latch off or malfunction. When the output shorts to ground at fault condition, the direct path causes the inductor current running away, the converter active components damages, and the catastrophic failure at load circuit.

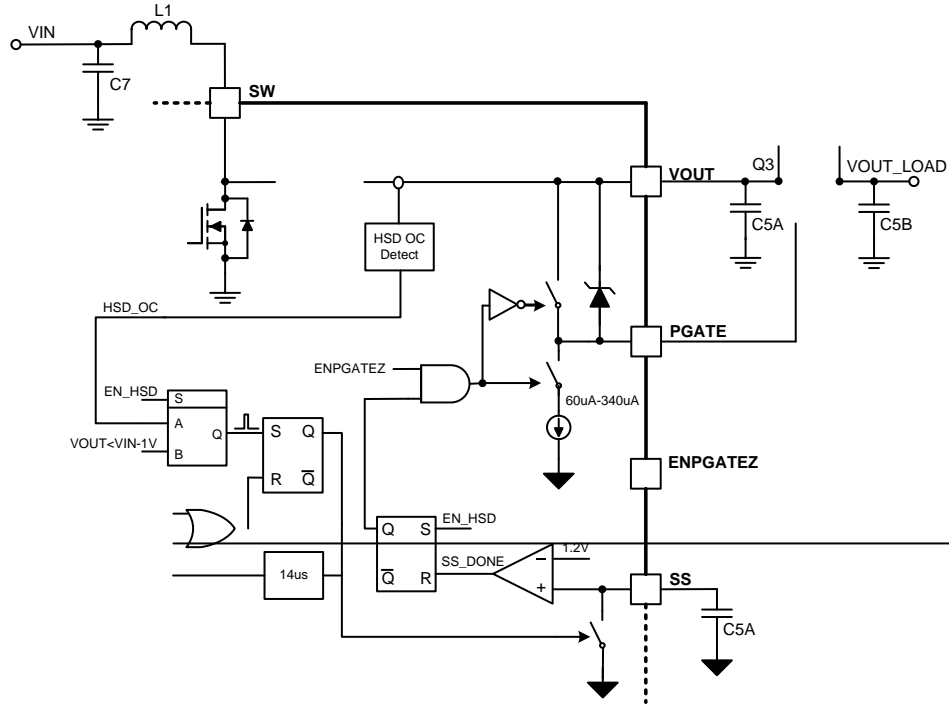

To address the above issues, the SCT12A1 provides a solution to insert an external P-channel MOSFET to disconnect the load from the converter output in application as shown in Figure 13. Choosing a lower  $R_{ds(on)}$  of the disconnection P-channel MOSFET Q3 reduces impact on the efficiency. The source of Q3 needs connect to VOUT pin. Output capacitor is required at both VOUT pin and the source of P-channel MOSFET to maintain the loop stability.

In Figure 13, connecting ENPGATEZ pin to ground enables load disconnection features of SCT12A1. PGATE pin connecting to gate of Q3 has a constant sink current pulling down capability and a resistance pulling up capability. During SCT12A1 starting up, internal circuitry softly starts up of P-channel MOSFET. When gate-source voltage of external P-channel MOSFET is lower than the threshold voltage, the Q3 is turned on and the load is connected to VOUT pin. The source-gate voltage of external P-channel MOSFET is clamped up to 8V when the P-channel MOSFET is fully turned on.

To detect if SCT12A1 has serve over loading or output hard short condition, the SCT12A1 has the current sensing scheme on internal high-side MOSFET during its turn-on state as shown Figure 13. When the high side MOSFET over current is detected, SS pin is discharged to ground and the external P-channel MOSFET is turned off immediately. The load is disconnected from the converter output. When high-side MOSFET is turned off, the SCT12A1 compares the VIN and VOUT, if VOUT is lower than VIN 1V, the SCT12A1 shuts off the external P-channel MOSFET and disconnect the load immediately as well.

If serve over current happens or output shorts to ground, the SCT12A1 minimizes the power dissipation by implementing hiccup mode as shown in Figure 14. For example, when internal high-side MOSFET over current triggers load disconnection protection, SS pin resets and the boost converter stops switching. After SS pin starts charging and reaches 1.2V, boost converter resumes to normal switching and starts to turn on P-channel MOSFET again. The hiccup time can be calculated with external capacitance on SS pin as shown in equation 1. If the fault condition disappears, the SCT12A1 resumes to normal operation automatically.

In extreme application case, starting up SCT12A1 with huge output capacitor C5B and heavy load might cause over current protection. Increasing C5A capacitance accordingly enables startup normally.

**Figure 13. Load Disconnection Control**

**Figure 14. Hiccup Mode Sequence**

## Over Voltage Protection and Minimum On-time

The SCT12A1 features both VOUT pin over voltage protection and the FB pin over voltage protection. If the VOUT pin is above 15.4V typical or FB pin voltage exceeds 1.32V typical, the device stops switching immediately until the VOUT pin drops below 15.2 V or FB pin voltage drops below 1.26V. The OVP function prevents the connected output circuitry from un-predictive overvoltage.

The low-side MOSFET has minimum on-time 150ns typical limitation. While the device is operating at minimum on time and further increasing Vin pushed output voltage beyond regulation point. With output and feedback over voltage protection, the converter skips pulse with turning off high-side MOSFET and prevents output running higher to damage the load.

## Forced PWM and PFM Modes

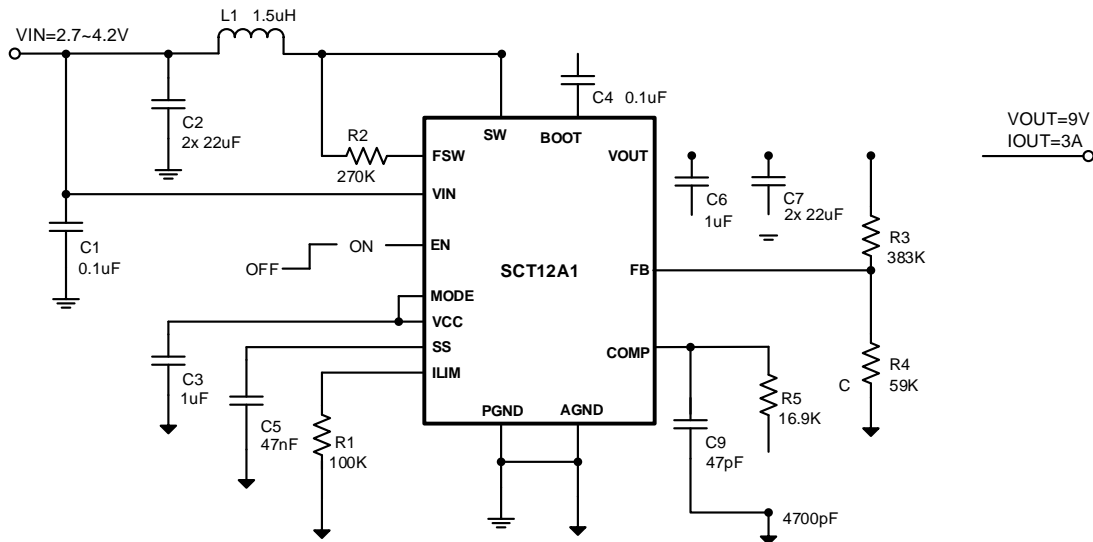

Connecting MODE pin to ground, the SCT12A1 forces the device operating at forced Pulse Width Modulation (PWM) mode with pseudo-fixed switching frequency regardless loading current. Operating in PWM mode can avoid the possible audible noise caused by lower frequency in PFM mode at light load. When the load current approaches zero, the high-side MOSFET current crosses zero and sinks current from output to maintain the constant output. Hence power efficiency in light load is much lower than heavy load.

Floating MODE pin or connecting MODE pin to VCC, the SCT12A1 works at Pulse Frequency Modulation (PFM) mode to improve the power efficiency in light load. As the load current decreasing, the COMP pin voltage decreases as resulting the inductor current down. With the load current further decreasing, the COMP pin voltage decreases and be clamped to a voltage corresponding to the ILIM/12. The converter extends the off time of high-side MOSFET Q2 to reduce the average delivered current to output. The switching frequency is lower and varied depending on loading condition. In PFM mode, the peak inductor current is fixed at around 1A and the output voltage is regulated 0.7% higher than the setting output voltage. When the inductor current decreased to zero, zero-cross detection circuitry on high-side MOSFET Q2 forces the Q2 off until the beginning of the next switching cycle. The boost converter does not sink current from the load at light load.

## Thermal Shutdown

Once the junction temperature in the SCT12A1 exceeds 150C, the thermal sensing circuit stops switching until the junction temperature falling below 130C, and the device restarts. Thermal shutdown prevents the damage on device during excessive heat and power dissipation condition.

## Switching Frequency

The resistor connected from FSW to SW sets switching frequency of the converter. The resistor value required for a desired frequency can be calculated using equation 2. High frequency can reduce the inductor and output capacitor size with the tradeoff of more thermal dissipation and lower efficiency.

$$R_{FSW} = \frac{V_{IN}}{f_{SW} \cdot C_{FREQ}}$$

where:

- $f_{SW}$  is the desired switching frequency
- $T_{DELAY} = 90 \text{ ns}$
- $C_{FREQ} = 34 \text{ pF}$
- $V_{IN}$  is the input voltage
- $V_{OUT}$  is the output voltage

2000 KHz	48.7 K

## Peak Current Limit

Using equation 3 the correct external resistor at ILIM pin sets the peak input current. For a typical current limit of 12A, the resistor value is 100K . The minimum current limit must be higher than the required peak switch current at lowest input voltage and the highest output power not to hit the current limit and still regulate the output voltage.

$$R_{LIM} = \frac{V_{IN}}{I_{LIM}}$$

where:

- $I_{LIM}$  is the peak current limit
- $R_{LIM}$  is the resistance of ILIM pin to ground

## Output Voltage

The output voltage is set by an external resistor divider R3 and R4 in typical application schematic. A minimum current of typical 20uA flowing through feedback resistor divider gives good accuracy and noise covering. The value of R3 can be calculated by equation 4.

$$R_3 = \frac{V_{OUT} \cdot R_4}{V_{REF}} \quad (4)$$

where:

- $V_{REF}$  is the feedback reference voltage, typical 1.2V

## Inductor Selection

The performance of inductor affects the power supply's steady state operation, transient behavior, loop stability, and boost converter efficiency. The inductor value, DC resistance, and saturation current influences both efficiency and the magnitude of the output voltage ripple. Larger inductance values reduces inductor current ripple and therefore leads to lower output voltage ripple. For a fixed DC resistance, a larger value inductor yields higher efficiency via reduced RMS and core losses. However, a larger inductor within a given inductor family will generally have a greater series resistance, thereby counteracting this efficiency advantage.

Inductor values can have  $\pm 20\%$  or even  $\pm 30\%$  tolerance with no current bias. When the inductor current approaches saturation level, its inductance can decrease 20% to 35% from the value at 0-A current depending on how the inductor vendor defines saturation. When selecting an inductor, choose its rated current especially the saturation current larger than its peak current during the operation.

To calculate the current in the worst case, use the minimum input voltage, maximum output voltage, maximum load current and minimum switching frequency of the application, while considering the inductance with -30% tolerance and low-power conversion efficiency.

For a boost converter, calculate the inductor DC current as in equation 5

$$\text{Equation 5} \quad (5)$$

Where

- $V_{OUT}$  is the output voltage of the boost converter
- $I_{OUT}$  is the output current of the boost converter
- $V_{IN}$  is the input voltage of the boost converter

### Input Capacitor Selection

For good input voltage filtering, choose low-ESR ceramic capacitors. A 0.1μF ceramic bypass capacitor is recommended to be placed as close as possible to the VIN pin of the SCT12A1. A ceramic capacitor of more than 1.0μF is required at the VCC pin to get a stable operation of the internal LDO.

For the power stage, because of the inductor current ripple, the input voltage changes if there is parasitic inductance and resistance between the power supply and the inductor. It is recommended to have enough input capacitance to make the input voltage ripple less than 100mV. Generally, 2x 22μF input capacitance is recommended for most applications. Choose the right capacitor value carefully by considering high-capacitance ceramic capacitors DC bias effect, which has a strong influence on the final effective capacitance.

### Output Capacitor Selection

For small output voltage ripple, choose a low-ESR output capacitor like a ceramic capacitor. Typically, three 22μF ceramic output capacitors work for most applications. Higher capacitor values can be used to improve the load transient response. Due to a capacitor's derating under DC bias, the bias can significantly reduce capacitance. Ceramic capacitors can lose most of their capacitance at rated voltage. Therefore, leave margin on the voltage rating to ensure adequate effective capacitance. From the required output voltage ripple, use the equation 8 and 9 to calculate the minimum

The next step is to choose the loop crossover frequency,  $f_c$ . The higher frequency that the loop gain stays above zero before crossing over, the faster the loop response is. It is generally accepted that the loop gain cross over no higher than the lower of either 1/10 of the switching frequency,  $f_{sw}$ , or 1/5 of the RHPZ frequency,  $f_{RHPZ}$ .

Then set the value of R5, C8, and C9 in typical application circuit by following these equations.

$$\text{_____} \quad (15)$$

where

- $f_c$  is the selected crossover frequency.

$$\text{_____} \quad (16)$$

$$\text{_____} \quad (17)$$

If the calculated value of C9 is less than 10pF, it can be left open. Designing the loop for greater than 45° of phase margin and greater than 10-dB gain margin eliminates output voltage ringing during the line and load transient.

### Layout Guideline

The regulator could suffer from instability and noise problems without careful layout of PCB. Radiation of high-frequency noise induces EMI, so proper layout of the high-frequency switching path is essential. Minimize the length and area of all traces connected to the SW pin, and always use a ground plane under the switching regulator to minimize coupling. The input capacitor needs to be close to the VIN pin and ground pad to reduce the input supply ripple. The placement and ground trace for C6 is critical for the performance of SW ringing voltage. Place capacitor C6 as close to VOUT pins and power ground pad as possible to reduce high frequency ringing voltage on SW pin. Connect ENPGATEZ pin to power ground pad under IC to reduce the ground trace impedance of C6, if ENPGATEZ grounding.

The layout should also be done with well consideration of the thermal. The center thermal pad should always be soldered to the board for mechanical strength and reliability, using multiple thermal vias underneath the thermal pad. The bottom layer is a large ground plane connected to the PGND plane and AGND plane on top layer by vias. Since thermal pad is electrical power ground of the device, improper soldering thermal pad to ground plate on PCB will cause SW higher ringing and overshoot besides downgrading thermal performance. It is recommended 8mil diameter drill holes of thermal vias, but a smaller via offers less risk of solder volume loss. On applications where solder volume loss thru the vias is of concern, plugging or tenting can be used to achieve a repeatable process.

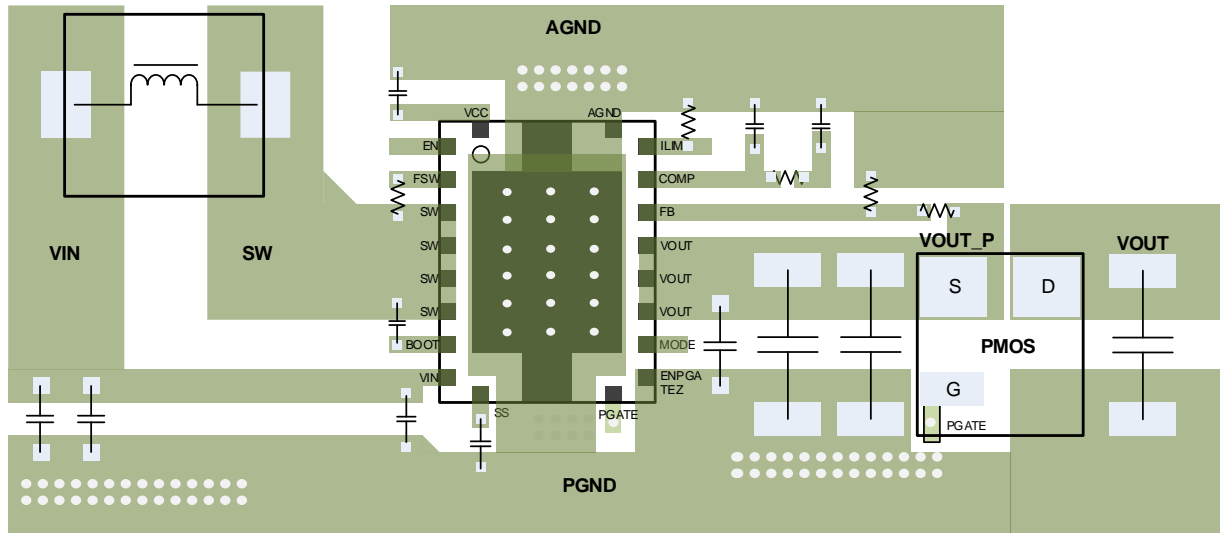

Figure 26. PCB Layout Example Top Layer

## Thermal Considerations

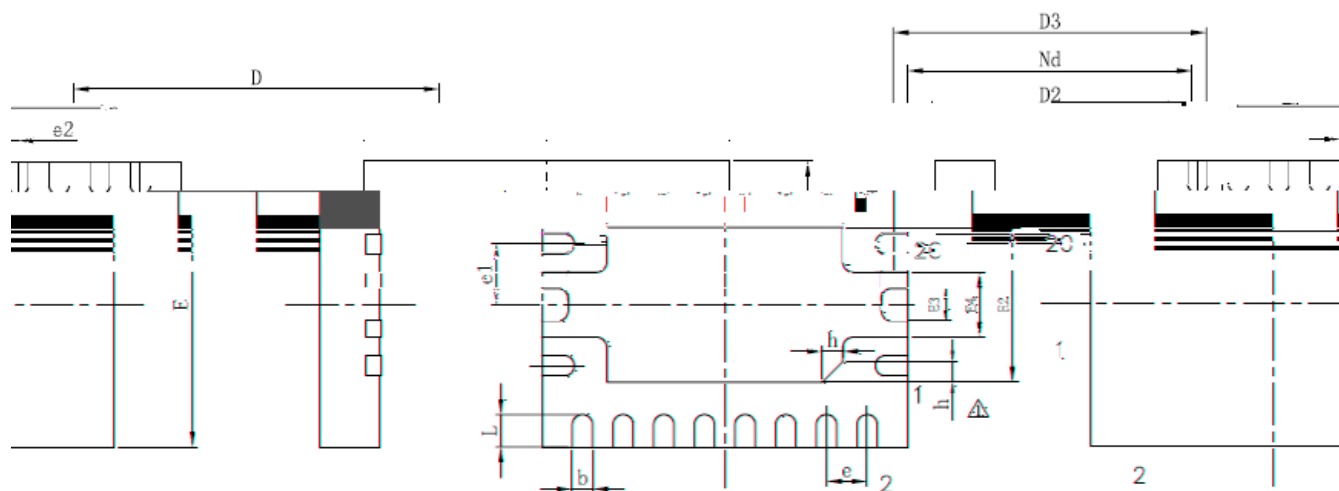

The maximum IC junction temperature should be restricted to 125°C under normal operating conditions. Calculate the maximum allowable dissipation,  $P_{D(max)}$ , and keep the actual power dissipation less than or equal to  $P_{D(max)}$ . The maximum-power-dissipation limit is determined using Equation 18.

(18)

where

- $T_A$  is the maximum ambient temperature for the application.
- $R_{JA}$  is the junction-to-ambient thermal resistance given in the Thermal Information table.

SCT12A1 DFN package includes a thermal pad that improves the thermal capabilities of the package. The real junction-to-ambient thermal resistance  $R_{JA}$  of the package greatly depends on the PCB type, layout, thermal pad connection and environmental factor. Using thick PCB copper and soldering the thermal pad to a large ground plate enhance the thermal performance. Using more vias connects the ground plate on the top layer and bottom layer around the IC without solder mask also improves the thermal capability.
